Collapse of Kaluza-Klein Bubbles

Steven Corley¹ and Ted Jacobson²

Department of Physics, University of Maryland, College Park, MD 20742-4111

Abstract

Kaluza-Klein theory admits “bubble” configurations, in which the circumference of the fifth dimension shrinks to zero on some compact surface. A three parameter family of such bubble initial data at a moment of time-symmetry (some including a magnetic field) has been found by Brill and Horowitz, generalizing the (zero-energy) “Witten bubble” solution. Some of these data have negative total energy. We show here that all the negative energy bubble solutions start out expanding away from the moment of time symmetry, while the positive energy bubbles can start out either expanding or contracting. Thus it is unlikely that the negative energy bubbles would collapse and produce a naked singularity.

1 Introduction

Negative energy initial data at a moment of time-symmetry have been found[2, 3] in five-dimensional Kaluza-Klein theory, with the spatial topology $(S^2 \times R^2)$ of the (zero-energy) “Witten bubble” solution[4]. Since negative mass solutions are typically associated with naked singularities, one naturally wonders whether the time evolution of the negative energy bubble data might produce a naked singularity. If the bubble expands, this seems unlikely, however if it were to collapse, the formation of a naked singularity would seem quite plausible.

Another reason to ask if negative energy bubbles can collapse is related to the second law of black hole thermodynamics. If one had a localized negative energy configuration it could be tossed into a black hole, thus decreasing the mass of the hole. Although we have not thought carefully about black hole entropy in Kaluza-Klein theory, it is plausible that decreasing the mass would decrease the entropy of the hole, thus violating the classical second law of black hole mechanics. If the bubble were to expand fast enough however, it would not be possible to get it into the black hole, so the existence of this negative energy configuration would not threaten the second law.

The Witten bubble solution is known in closed form for all time (it is just an analytic continuation of the five dimensional Schwarzschild solution), and is known to expand exponentially away from a moment of time symmetry. In this paper we will examine the class of initial data found by Brill and Horowitz in Ref. [3], for bubbles in both vacuum and electrovac Kaluza-Klein theory. Although the time evolution of these data is not known in closed form, we will establish that all the negative energy bubble solutions at least *start out* expanding, while the positive energy bubbles can start out either expanding or contracting.

Our conventions are those of Ref. [1].

2 Bubble data

All the bubbles we will discuss have three-dimensional spherical symmetry, in addition to translational symmetry in the fourth, compact, spatial dimension. Thus, the initial spatial line element has the form

$$^{(4)}ds^2 = U d\sigma^2 + g_{rr} dr^2 + g_{\theta\theta} (d\theta^2 + \sin^2\theta d\phi^2), \quad (1)$$

where U , g_{rr} and $g_{\theta\theta}$ are functions of r only. The circumference of the compact dimension approaches a constant value at large r . As we come in from infinity, this circumference changes with U , and eventually U shrinks to zero at $r = r_+$, where the “bubble” is said to be located. The manifold is smooth at the bubble provided the period P of the σ coordinate is chosen so as to avoid a conical singularity there. Values of r less than r_+ are not relevant—the manifold has a “hole” in it. For a fixed value of σ , the 3-topology is R^3 minus an open ball. For fixed θ and ϕ , one has the r - σ plane, in the shape of a semi-infinite “cigar”. Thus the spatial topology is $S^2 \times R^2$.

The bubble solution exhibited by Witten[4] is obtained by analytic continuation of the five dimensional Euclidean Schwarzschild solution:

$$ds^2 = \left(1 - \frac{R^2}{r^2}\right) d\sigma^2 + \left(1 - \frac{R^2}{r^2}\right)^{-1} dr^2 + r^2 \left(d\chi^2 + \sin^2\chi (d\theta^2 + \sin^2\theta d\phi^2)\right), \quad (2)$$

where σ is a periodic coordinate of range $2\pi R$. At large r (2) approaches the standard Kaluza-Klein vacuum $M^4 \times S^1$, where M^4 is Minkowski spacetime, with spatial topology $R^3 \times S^1$. The $\chi = \pi/2$ slice of (2) is an extremal hypersurface with the bubble topology $S^2 \times R^2$ described above, with the bubble “surface” located at $r = R$. Witten observed that the Euclidean Schwarzschild solution thus describes an instanton mediating decay of the standard Kaluza-Klein vacuum, via a topology changing tunneling process, to the zero energy bubble configuration. The classical, Lorentzian evolution of the bubble solution starting from the initial data given by the $\chi = \pi/2$ slice of (2) is obtained by the analytic continuation $\chi \rightarrow it + \pi/2$. This yields the exponentially expanding bubble solution

$$ds^2 = -r^2 dt^2 + \left(1 - \frac{R^2}{r^2}\right) d\sigma^2 + \left(1 - \frac{R^2}{r^2}\right)^{-1} dr^2 + r^2 \cosh^2 t (d\theta^2 + \sin^2\theta d\phi^2), \quad (3)$$

which is obviously symmetric in time about $t = 0$.

The vacuum bubble data of Brill and Horowitz[3] are obtained from the *four*-dimensional Euclidean Reissner-Nordström solution. Since the electromagnetic stress-energy tensor is tracefree in four dimensions, the Ricci scalar vanishes for these metrics, so they are solutions of the initial value constraint equations for the *five*-dimensional Einstein equation with vanishing extrinsic curvature. The electrovac data of [3] provide a one parameter generalization of the vacuum data, including a 5-dimensional magnetic field given by the vector potential $A = k(r_+^{-2} - r^{-2}) d\sigma$ with k a constant.

These bubble data are of the form (1), with $g_{rr} = U^{-1}$, $g_{\theta\theta} = r^2$, and

$$U = 1 - \frac{2m}{r} + \frac{b}{r^2} - \frac{4k^2}{3r^4}, \quad (4)$$

with m and b constants. The total ADM energy of the corresponding space-times is given by $m/2$ [3, 5] (in units with the reduced 4-dimensional gravitational coupling constant 4G equal to unity.)

The bubble surface, if it exists, is given by the largest root of the equation $U(r_+) = 0$. If there is a bubble, values of r less than r_+ are not part of the spacetime. Regularity of the geometry at r_+ requires that the period P of σ be given by $P = 4\pi/U'(r_+)$. In the vacuum case ($k = 0$) one finds $r_+ = m + \sqrt{m^2 - b}$. No simple expression for r_+ exists in the electrovac case.

For the electrovac case $k^2 \neq 0$, (4) yields a bubble for all m and b . For the vacuum case $k^2 = 0$, it is bubbular for $m > 0$ provided $b < m^2$, and for $m \leq 0$ provided $b < 0$. The $m = 0$, $k^2 = 0$ data corresponds to the Witten bubble, with $b = -R^2$. For $m > 0$, U increases monotonically from zero at the bubble to unity at infinity. For $m < 0$, U increases monotonically from zero at the bubble to a maximum, then decreases to unity at infinity. (In the vacuum case, the maximum is equal to $1 + |m^2/b|$, and is located at $r = |b/m|$.) For $m = 0$, U is monotonically increasing if $b \leq 0$, and has a maximum if $b > 0$.

3 Collapsing or expanding?

As we do not possess the time dependent solutions with initial data given by (1) and (4), we shall presently determine only whether the bubble starts out collapsing or expanding from the moment of time symmetry. Since it is stationary at that moment, this amounts to determining the sign of the second time derivative of the bubble area A evaluated at the initial moment.

The bubble surface is located where the Killing field generating rotations around the fifth dimension vanishes. Now in general, a submanifold defined by the zeros of a Killing field is totally geodesic. Therefore, by spherical symmetry, the worldline of a point at fixed angles on the bubble surface must be a geodesic. For convenience, let us choose Gaussian normal coordinates $(t, r, \theta, \phi, \sigma)$, with $t = 0$ the moment of time symmetry. Then such a geodesic on the bubble stays at fixed r , and t measures proper time along it.

If we write the angular part of the line element as $g_{\theta\theta}(r, t) (d\theta^2 + \sin^2\theta d\phi^2)$, the area of the bubble is given by $A(t) = 4\pi g_{\theta\theta}(r_+, t)$. (At the moment of time symmetry we have $g_{\theta\theta}(r, 0) = r^2$.) We thus have

$$\ddot{A} = 4\pi g_{\theta\theta, tt}, \quad (5)$$

where the partial derivative is to be evaluated at the bubble surface, and the dot indicates derivative with respect to proper time along the bubble surface world line.

There are now several ways one can determine $g_{\theta\theta, tt}$ at the moment of time symmetry. For instance, it is straightforward to simply write out the Einstein equation in Gaussian normal coordinates. Equivalently, one may use the standard ADM evolution equations with unit lapse and vanishing shift. But the most convenient and informative technique is probably to employ the geodesic deviation equation, applied to the radial geodesic congruence at the bubble surface. This tells us that, since the geodesics remain at fixed r, θ, ϕ, σ , the second covariant derivative of their separation distance L is given by $\ddot{L} = -R^\theta_{\theta t} L$, where, e.g., $L = g_{\theta\theta}^{1/2} d\theta$ for $d\phi = 0$. We thus obtain

$$\begin{aligned} g_{\theta\theta, tt} &= -2R_{\theta t \theta t} \\ &= 2(R_{\theta\theta} - {}^{(4)}R_{\theta\theta}) \\ &= 2(T_{\theta\theta} - \frac{1}{3}Tg_{\theta\theta} - {}^{(4)}R_{\theta\theta}), \end{aligned} \quad (6)$$

where ${}^{(4)}R_{ij}$ is the Ricci tensor of the spatial metric at the moment of time symmetry. In the second equality we have used the fact that on a hypersurface of vanishing extrinsic curvature, the intrinsic curvature tensor is equal to the projected spacetime curvature. In the third equality, we have used the 5-dimensional Einstein equation $R_{ab} - \frac{1}{2}Rg_{ab} = T_{ab}$. The problem is now reduced to simply evaluating (6) using the bubble initial data.

For the action $\int (-g)^{1/2} (R - F^2)$ used by Brill and Horowitz, one finds $T_{ab} = 2F_{ac}F_b{}^c - \frac{1}{2}g_{ab}F^2$. Since the data for F_{ab} includes only a magnetic field component $F_{r\sigma} = -2k/r^3$, one finds at the moment of time symmetry $R_{\theta\theta} = -\frac{2}{3}g_{\theta\theta}F_{r\sigma}^2 = -\frac{8}{3}k^2/r^4$. On the other hand, for the bubble metrics (1), (4) of interest, we have ${}^{(4)}R_{\theta\theta}|_{t=0} = [r(1-U)]_{,r} = b/r^2 - 4k^2/r^4$. Thus (5) together with (6) yields

$$\begin{aligned} \ddot{A} &= 8\pi(-\frac{b}{r_+^2} + \frac{4k^2}{3r_+^4}) \\ &= 8\pi(1 - \frac{2m}{r_+}). \end{aligned} \quad (7)$$

We conclude from (7) that the negative energy bubbles all begin expanding from a moment of time symmetry. Positive energy bubbles either start out expanding or contracting, depending on whether r_+ is greater than or less than $2m$ respectively. Unfortunately, our analysis provides no insight into “why” the negative energy bubbles start out expanding, and we do not know whether the result generalizes beyond the particular initial data we have considered.

Note that we have *not* determined whether a bubble that starts out expanding (or contracting) will continue to do so for all time. Could a bubble start out expanding, come to rest, and then turn around and collapse? Or could a bubble collapse to a minimum size, and then bounce back? It might seem that our results already show this is not possible, since the maximum of expansion or minimum of contraction would be another moment of time symmetry, which we have already analyzed. However, the data at the new moment of time symmetry need not be in the three parameter family found by Brill and Horowitz. For example, in the vacuum case, all we know is that $R_{ab} = 0$, ${}^{(4)}R = 0$, and the total energy is conserved. We do not know however if this fixes the sign of ${}^{(4)}R_{\theta\theta}$ at the bubble. According to equation (6) this sign is what determines whether the bubble expands or contracts.

It is a pleasure to thank Dieter Brill for helpful comments on a draft of this paper. This work was supported in part by NSF Grant PHY91-12240.
